Among patients diagnosed with cerebral aneurysms, the reported incidence of multiple intracranial aneurysms is between 14% and 34%.1-8) In 20 to 40% of these patients, the aneurysms are bilateral.1-8) Given the actuarial risk of rupture, the surgical goal in patients with bilateral aneurysms is clipping of all lesions. The first craniotomy should be performed on the side of the ruptured aneurysm. The second craniotomy, to be done some time later, should be performed in order to exclude the incidental aneurysm from the circulation. In patients with bilateral supratentorial aneurysms, surgical clipping of all aneurysms via a unilateral approach would obviate the need for a second operation. Patients harboring bilateral supratentorial aneurysms can be approached via the contralateral pterional approach in selected cases.

Case

A 48-year-old woman presented with a complaint about loss of consciousness for 1 minute. Hunt and Hess grade was 0 and Fischer grade was I. Neurological examinations disclosed no abnormality. She was found to have two aneurysms at the left middle cerebral artery and the right anterior choroidal artery. The main direction of the anterior choroidal artery aneurysm was posterior. A direct clipping was performed via the left pterional approach. After the left middle cerebral artery aneurysm was clipped, the contralateral anterior choroidal artery aneurysm was further exposed and successfully clipped through the contralateral carotico-optic space. The author reports a case of bilateral supratentorial aneurysms that was successfully clipped via unilateral pterional approach, thus avoiding a second craniotomy.

Key words : cerebral aneurysm, bilateral supratentorial aneurysms, unilateral approach
artery aneurysm was posterior (Fig. 1B). The size was 1.9 * 1.7 * 2.0 * 2.2 mm. Both of the aneurysms are not feasible for coil embolization, so direct clipping was scheduled.

With the patient supine, a left frontotemporal craniotomy was performed. The parachiasmatic cistern was first approached and cut to evacuate the cerebrospinal fluid. The left sylvian dissection was performed, and the left middle cerebral artery bifurcation aneurysm was exposed (Fig. 2A). Small daughter sac was seen at the dome of aneurysm. Clipping of the left middle cerebral artery bifurcation aneurysm was successfully done. The prechiasmatic cistern was further dissected to the right side to expose the right optic nerve. The medial surface of the contralateral distal carotid artery was explored superior and lateral to the optic chiasm. The contralateral carotid artery segment lateral to the chiasm was identified and the dissection carried distally. The contralateral anterior choroidal artery aneurysm could be easily indentified without retracting the optic nerve (Fig. 2B). The contralateral anterior choroidal artery aneurysm was further exposed and successfully clipped through the contralateral carotico-optic space (Fig. 3). The wound was closed as usual. The whole procedure took 3 hours, and the patient experienced minimal blood loss.

The postoperative course was good and the patient was discharged 7 days after surgery. She displayed no neurological deficit. Postoperative cerebral angiography was...
done and showed that aneurysm was disappeared (Fig. 4A and 4B).

Fig. 4. Postoperative cerebral angiograms show complete obliteration of aneurysms at bifurcation of the left middle cerebral artery (A) and the right anterior choroidal artery aneurysm (B).

Discussion

Since Yasargil et al. first reported a case of an internal carotid-ophthalmic artery aneurysm clipped contralaterally, several authors have used this approach in selected patients with bilateral supratentorial aneurysms. The contralateral approach to ophthalmic segment aneurysms is very well described, even to the point that it is included in standard neurosurgical textbook.11) The openings of the ipsilateral sylvian and carotid cisterns, of the chiasmatic and lamina terminalis, and of the contralateral carotid and the sylvian vallecula cisterns create a tunnel-like space that allows full exposure of the contralateral anterior perforated substance and of the vascular structures related to it. The microscope rotates laterally to follow the axis of the tunnel as the cisternal opening proceeds to the opposite side. The opening of the contralateral sylvian vallecula cistern completes the exposure.16)

In order to address the amenability for contralateral clipping the size, shape, and projection of the aneurysm and its relationships with the surrounding brain should be taken into consideration. The contralateral clipping of anterior circulation aneurysms should only be performed when brain conditions are ideal. Acute stage surgery for contralateral aneurysms should be avoided as brain conditions can make the surgery very difficult. During the acute stage the brain is frequently swollen and dissection of the cisterns is often very difficult. In such conditions the necessity for excessive brain retraction seems to be the rule and marked injury to the frontal lobes is to be expected. Acute stage surgery should thus be reserved to the aneurysm that has ruptured and eventually to the remainder aneurysms if brain conditions are favorable.1, 16-21)

The triangle defined by the lateral border of the contralateral optic nerve (chiasm and tract), the inferior aspect of the A1 segment of the contralateral anterior cerebral artery, and the medial aspect of the distal contralateral carotid artery define the contralateral opticocarotid space. Lateral displacement of the carotid artery through this triangle located superior to the optic apparatus allows exploration of the medial aspect of the contralateral carotid. This corridor affords the best opportunity to access the contralateral anterior choroidal origin. In the setting of a long supraclinoid carotid or prefixed chiasm, the origin of the posterior communicating artery also can be accessed through this triangle.18-19)

Posterior communicating and choroidal segments aneurysms usually project posterior and laterally. Identification of the aneurysm neck and of the origins of the posterior communicating and anterior choroidal arteries is usually difficult as they are partially hidden by the carotid artery and by the optic nerve. The optic nerve and chiasm usually
One of the complications of this technique is the lesion of the olfactory tract. In such cases, it is very important to be careful during the dissection and try not to use brain retractors so as to preserve olfaction. It is also very relevant to stress that sometimes it is very risky to perform an extensive dissection after subarachnoid hemorrhage mainly between the fourth and the ninth day as the brain could be rather fragile and edematous. It is also important to mention that the unilateral approach to bilateral aneurysms should be reserved for very experienced vascular neurosurgeons.\textsuperscript{16-18)}

Surgery is not indicated in cases of large or giant contralateral aneurysms because the approach - narrow and deep - does not only impair dissection of the aneurysm but also prevents the use of multiple clips. de Sousa AA commented that surgery was not indicated for contralateral MCA aneurysms with a diameter larger than 10mm.\textsuperscript{1, 19)}

\textbf{Conclusion}

The author reports a case of bilateral supratentorial aneurysms that was successfully clipped via unilateral pterional approach, thus avoiding a second craniotomy.
